Abstract

It has been proposed some time ago that the large N –limit can be understood as a “classical limit”, where commutators in some sense approach the corresponding Poisson brackets. We discuss this in the light of some recent numerical results for an $SU(N)$ gauge model, which do not agree with this “classicality” of the large N –limit. The world sheet becomes very crumpled. We speculate that this effect would disappear in supersymmetric models.

To Holger Bech Nielsen on his 60th birthday

In the 1970ies Holger and I discussed the confinement problem quite a lot. In those days the picture of confinement by means of a string connecting the quarks became more and more accepted. It was known that the Nambu-Goto action could be written as a square root of the Poisson bracket squared. One of the subjects we discussed was whether somehow the Poisson bracket was related to the commutator like in quantum mechanics, in some limit. However, we did not gain any insight in this. After the work by Eguchi and Kawai it became of course clear that the relevant limit was the large N limit, where the action could be expressed in terms of commutators. Later on Hoppe [1] constructed a very suggestive relation between Poisson brackets and commutators. This was then used in ingenious ways by a number of authors [2, 3, 4], in connection with the Eguchi-Kawai formulation of the large N theory.

To give a brief review of this approach, let us consider $SU(N)$ with the gauge field A_μ and the generators $l_{\mathbf{k}}, \mathbf{k} = (k_1, k_2)$,

$$(A_\mu)_i^j = \sum_{\mathbf{k}} a_\mu^{\mathbf{k}} (l_{\mathbf{k}})_i^j, \quad (1)$$

where $a_\mu^{\mathbf{k}}$ are expansion coefficients to be integrated in functional integrals. This expansion can be compared to the one for a string variable $X_\mu(\sigma, \tau)$,

$$X_\mu(\sigma, \tau) = \sum_{\mathbf{k}} a_\mu^{\mathbf{k}} e^{i\mathbf{k}\sigma}, \quad (2)$$

with $\sigma = (\sigma, \tau)$. The variables X_μ are the Weyl transform of the matrices A_μ . The generators can be constructed explicitly in terms of the Weyl matrices, and have the commutation relation

$$[l_{\mathbf{k}_1}, l_{\mathbf{k}_2}] = i \frac{N}{2\pi} \sin\left(\frac{2\pi}{N} \mathbf{k}_1 \times \mathbf{k}_2\right) l_{\mathbf{k}_1 + \mathbf{k}_2} \rightarrow i (\mathbf{k}_1 \times \mathbf{k}_2) l_{\mathbf{k}_1 + \mathbf{k}_2} \quad (3)$$

for $N \rightarrow \infty$, where $\mathbf{k}_1 \times \mathbf{k}_2 = (k_1)_1(k_2)_2 - (k_2)_1(k_1)_2$. This leads to a comparison of the commutator with the Poisson bracket. For example, one has

$$[A_\mu, A_\nu] = i \frac{N}{2\pi} \sum_{\mathbf{k}, \mathbf{p}} a_\mu^{\mathbf{k}} a_\nu^{\mathbf{p}} \sin\left(\frac{2\pi}{N} \mathbf{k} \times \mathbf{p}\right) l_{\mathbf{k}_1 + \mathbf{k}_2}, \quad (4)$$

and

$$\{X_\mu(\sigma), X_\nu(\sigma)\} = i \sum_{\mathbf{k}, \mathbf{p}} a_\mu^{\mathbf{k}} a_\nu^{\mathbf{p}} (\mathbf{k} \times \mathbf{p}) e^{i(\mathbf{k} + \mathbf{p})\sigma}. \quad (5)$$

Using

$$\text{tr } l_{\mathbf{k}} l_{\mathbf{p}} \propto \delta_{\mathbf{k} + \mathbf{p}, \mathbf{0}}, \quad \int d^2\sigma e^{i(\mathbf{k} + \mathbf{p})\sigma} \propto \delta_{\mathbf{k} + \mathbf{p}, \mathbf{0}}, \quad (6)$$

one can derive that

$$\text{tr } [A_\mu, A_\nu]^2 \rightarrow \text{const.} \int d^2\sigma \{X_\mu, X_\nu\}^2, \quad (7)$$

where the constant (depending on N) can be removed by a suitable normalization, and where it was used that

$$\frac{N}{2\pi} \sin\left(\frac{2\pi}{N} \mathbf{k}_1 \times \mathbf{k}_2\right) \rightarrow \mathbf{k}_1 \times \mathbf{k}_2 \quad (8)$$

for $N \rightarrow \infty$, even *inside* the relevant sum over modes. In this sense the commutator approaches the Poisson bracket [2, 3, 4].

Unfortunately this argument, leading to a nice connection between strings and fields in the large N -limit, depends on performing the limit $N \rightarrow \infty$ inside sums over modes like in eq. (4). This is evidently valid if the low modes dominate, since the difference between $\sin x$ and the linear function x is considerable when x is not close to 0.

Recently Anagnostopoulos, Nishimura and the author [8] started to investigate numerically the mode-distribution for large N in a four-dimensional $SU(N)$ model with the partition function

$$\int dA_\mu \exp\left(\frac{1}{4g^2} \text{tr}[A_\mu, A_\nu]^2\right). \quad (9)$$

This model has been shown to exist [5, 6, 7]. The expectation value of the commutator squared

$$M = \langle \text{tr}[A_\mu, A_\nu]^2 \rangle, \quad (10)$$

can be found from a scaling argument [6] to be $N^2 - 1$, and we checked our numerical method by seeing that it leads very precisely to this result.

Then we computed the corresponding expectation value of the Poisson bracket by introducing the Weyl-transform¹ $X_\mu(\sigma)$ (defined on a torus) of A_μ , and we therefore found the behavior of

$$\langle P \rangle = \langle \int d^2\sigma \{X_\mu(\sigma), X_\nu(\sigma)\}^2 \rangle. \quad (11)$$

Here the normalization is such that if only the very lowest modes are kept, one has the result $\langle M \rangle = \langle P \rangle$. For the details of this construction, we refer to the paper [8]. One important point discussed in this paper is that the Poisson bracket is gauge dependent, and hence $\langle P \rangle$ is in general gauge dependent, in contrast to the gauge invariant $\langle M \rangle$. We have selected a gauge fixing analogous to the Landau gauge. Of course, one can anyhow argue that if the commutator really approaches the Poisson bracket, gauge invariance of the former implies gauge invariance of the latter, at least approximatively.

In our numerical calculations we took $N = 15, 25$, and 35 . The results were quite embarrassing. Keeping only a few modes, we got $\langle M \rangle \approx \langle P \rangle$, but including all modes these two quantities differ considerably: Whereas very precisely we find $\langle M \rangle = N^2 - 1$, it turns out that $\langle P \rangle$ rather grows like $O(N^4)$. Therefore the two expectation values do not at all agree, and the discrepancy actually increases with N . We can therefore say that in the model with the action (9), the Poisson bracket is not approximated by the commutator.

¹The Weyl transform $X_\mu(\sigma)$ of the matrix A_μ is given by $X_\mu(\sigma) \propto \sum_k \exp(ik\sigma) \text{tr}(l_k A_\mu)$

We also computed the average of the area of the world sheet,

$$\langle A \rangle = \langle \int d^2\sigma \sqrt{\{X_\mu(\sigma), X_\nu(\sigma)\}^2} \rangle. \quad (12)$$

It turns out that $\langle A \rangle \approx \langle M \rangle$. Thus, the expectation value of the Nambu-Goto action does indeed behave approximately as the commutator. This does, however, not show that the action (9) is approximately equal to the Nambu-Goto action, since we have computed only one moment of A .

The negative result given above shows that the question of whether the large N limit is a classical limit, depends on the dynamics, and a simple model like (9) is not able to suppress the higher modes, and hence one cannot use the limit (3) inside sums over modes. The string picture resulting from the behavior of $X_\mu(\sigma)$ turns out to be an extremely crumpled string, with an almost infinite (≈ 33) Hausdorff dimension. This is another way of seeing that higher modes are important, since dominance of lower modes would lead to a smooth string.

As pointed out in [8] the model (9) does exist in a world-sheet version, since the commutator can be replaced by star products of the X 's, so the action can be rewritten as

$$\int dX_\mu \exp \left[\frac{-1}{4g^2 N} \int d^2\sigma (X_\mu(\sigma) \star X_\nu(\sigma) - X_\nu(\sigma) \star X_\mu(\sigma))^2 \right], \quad (13)$$

which exists because the corresponding matrix model exists. The world sheet defined by this theory (with an infinite number of derivatives in the star product) is the same as before, and is thus extremely crumpled.

Thus the dynamical question of the existence of a “classical” large N -limit boils down to finding a rather smooth string, since any “violent” string would require higher modes. Presumably the QCD string is smooth. In this case the action (9) is replaced by a quenched action, which hopefully can manage to suppress the high modes. Another possibility is to take a supersymmetric version of (9), since supersymmetry in general makes strings more smooth: For example, in the vacuum energy the tachyon is removed by supersymmetry. For the simple bosonic string it was shown long time ago by Alvarez [9] that the bosonic string is very crumpled, and by the author [10] that the tachyon produces this crumpling. Alvarez’ formula for the free energy [9],

$$F = \frac{1}{2\pi\alpha'} T \sqrt{R^2 - R_c^2}, \quad (14)$$

can actually be interpreted [10] as a formula for the lowest tachyonic energy, with the tachyon mass squared being proportional to $-R_c^2$. The phenomenon of crumpling should thus not occur in the supersymmetric case. We hope that these questions will be investigated numerically for supersymmetric versions of (9) in the future.

Finally, I would like to take this opportunity to thank Holger for pleasant years of discussions of very many aspects of physics.
